ABSTRACT
We study the problem of formally verifying individual fairness of decision tree ensembles, as well as training tree models which maximize both accuracy and individual fairness. In our approach, fairness verification and fairness-aware training both rely on a notion of stability of a classifier, which is a generalization of the standard notion of robustness to input perturbations used in adversarial machine learning. Our verification and training methods leverage abstract interpretation, a well-established mathematical framework for designing computable, correct, and precise approximations of potentially infinite behaviors. We implemented our fairness-aware learning method by building on a tool for adversarial training of decision trees. We evaluated it in practice on the reference datasets in the literature on fairness in machine learning. The experimental results show that our approach is able to train tree models exhibiting a high degree of individual fairness with respect to the natural state-of-the-art CART trees and random forests. Moreover, as a by-product, these fairness-aware decision trees turn out to be significantly compact, which naturally enhances their interpretability.

1 INTRODUCTION
Nowadays, machine learning (ML) software assists or even automates decisions with far-reaching socio-economic impact, e.g., for credit scoring [29], recidivism prediction [14], or hiring tasks [41]. The widespread and ever-increasing adoption of ML-based decision-making tools raises concerns on their fairness properties [4, 31]. A number of recent cases have indeed shown that such tools may reproduce, or even reinforce, bias directly or indirectly present in the training data [9, 27, 33]. For this reason, the Artificial Intelligence Act [19] — a first legal framework on machine learning software proposed by the European Commission in April 2021 — imposes strict requirements to minimize the risk of discriminatory outcomes. Our work anticipates the need for methods and tools to facilitate the development of machine learning software that complies with this newly proposed regulation.

Several fairness verification and bias mitigation approaches for machine learning systems have been proposed in recent years, e.g., [1, 23, 39, 40, 43, 45, 46] among the others. However, most works focus on neural networks [39, 40, 43, 45] or on group-based notions of fairness [23, 46], e.g., demographic parity [18] or equalized odds [24]. These notions of group-based fairness require some form of statistical parity (e.g., between positive outcomes) for members of different protected groups (e.g., gender or race). On the other hand, they do not provide guarantees for individuals or other subgroups. By contrast, in this paper we focus on individual fairness [18], which intuitively requires that similar individuals in the population receive similar outcomes, and on decision tree ensembles [7, 20], which are commonly used for tabular datasets since they are easily interpretable ML models with high accuracy rates.

1.1 Contributions
We propose an approach for verifying individual fairness of decision tree ensembles, as well as for training tree models which maximize both accuracy and individual fairness.

Our methodology is based on the well-established framework of abstract interpretation [15, 16, 38] for designing computable, correct, and precise over-approximations of model computations. In this approach, model computations are over-approximated using an abstract domain, which defines a symbolic abstract representation of the concrete quantities being manipulated. Our technique over-approximates computations over input space regions containing similar individuals, and is fully parametric in the choice of the underlying abstract domain. More precisely, we use a product of two abstract domains:
(a) the well-known numerical abstract domain of hyper-rectangles (also known as boxes or intervals) [16], that represents exactly the standard notion of similarity between individuals based on the $L_\infty$ distance metric, and does not lose precision for the univariate split rules of type $x_i \leq k$, with $x_i$ feature and $k$ threshold, the most common split rules used in decision trees;

(b) a specific relational abstract domain which is able to represent precisely one-hot encoded categorical features, such as a feature $\text{color} \in \{\text{white}, \text{black}\}$ which is one-hot encoded by $\text{color}_{\text{white}}, \text{color}_{\text{black}} \in \{0,1\}$.

Our Fairness-Aware Tree Training method, called FATT, is designed as an extension of Meta-Silvae [37], a learning methodology for ensembles of decision trees based on a genetic training algorithm, which is able to train a decision tree for maximizing both its accuracy and its robustness to adversarial perturbations. Meta-Silvae in turn leverages a verification tool for robustness properties of decision trees based on abstract interpretation [36]. We demonstrate the effectiveness of our method FATT in training accurate and fair models on the standard datasets used in the literature on fairness in machine learning. Overall, the experimental results show that our fairness-aware tree models are on average between 35% and 45% more fair than naturally trained decision tree ensembles at an average cost of $\approx 3.6\%$ of accuracy. Moreover, it turns out that our tree models are orders of magnitude more compact and thus naturally easier to interpret. Finally, we show how our fairness-aware models can be used as “hints” for setting the size and shape hyper-parameters (i.e., maximum tree depth and minimum number of samples per leaf) when training standard decision tree models. As a result, this hint-based strategy is capable to output models that are about 20% more fair and just about 1% less accurate than standard models.

1.2 Related Work

The most related work to ours is by Aghaei et al. [1], Raff et al. [34] and Ruoss et al. [40].

By relying on the mixed-integer optimization learning approach by Bertsimas and Dunn [5], Aghaei et al. [1] put forward a framework for training fair decision trees for classification and regression. The experimental evaluation shows that this approach mitigates unfairness as modeled by their notions of disparate impact and disparate treatment at the cost of a significantly higher training computational cost. Their notion of disparate treatment is distance-based and thus akin to individual fairness with respect to the nearest individuals in a given dataset (e.g., the $k$-nearest individuals). In contrast, we consider individual fairness with respect to the nearest individuals in the input space, thus including individuals that are not necessarily part of a given dataset.

Raff et al. [34] propose a regularization-based approach for training fair decision trees as well as fair random forests. They consider both group fairness as well as individual fairness with respect to the $k$-nearest individuals in a given dataset, similarly to Aghaei et al. [1]. In their experiments they use a subset of the datasets that we consider in our evaluation (i.e., the Adult, German, and Health datasets). Our fair models have higher accuracy than theirs (i.e., between 2% and 5.5%) for all but one of these datasets (Health dataset). Interestingly, their models (in particular those with worse accuracy than ours) often have accuracy on par with a constant classifier due to the highly unbalanced label distribution of the datasets. Unfortunately, their tool does not appear to be available for further experimental comparison.

Finally, Ruoss et al. [40] have proposed an approach for learning individually fair data representations and training neural networks (rather than decision tree ensembles as we do) that satisfy individual fairness with respect to a given similarity notion. We use the same notions of similarity in our experiments (cf. Section 6.1).

More broadly, our work fits into the research ecosystem that is nowadays forming around the use of formal methods for the verification of machine learning software. We refer to Liu et al. [30] and Urban et al. [44] for recent surveys of this field.

The rest of the paper is organized as follows. In Section 2 we recall some basic notions on decision tree ensembles and abstract interpretation, while Section 3 provides our setting of individual fairness. In Section 4 we describe our formal verification method of the individual fairness of tree ensembles, which is then exploited in Section 5 by the fairness-aware tree training algorithm FATT. Section 6 describes our implementation of FATT and the results of our experimental evaluation. Section 7 concludes.

2 BACKGROUND

2.1 Classifiers

Given an input space $X \subseteq \mathbb{R}^d$ of numerical vectors and a finite set of labels $L = \{y_1, \ldots, y_m\}$, a classifier $C : X \rightarrow \phi_+(L)$, where $\phi_+(L)$ is the set of all nonempty subsets of $L$, associates at least one label to every input in $X$. A training algorithm takes as input a dataset $D \subseteq X \times L$ and outputs a classifier $C_D : X \rightarrow \phi_+(L)$ which optimizes a given objective function, e.g., the Gini index or the entropy-based information gain for decision trees.

Categorical features can be converted into numerical ones by one-hot encoding, where a single feature with $k > 2$ possible distinct categories $\{c_1, ..., c_k\}$ is replaced by $k$ new binary features with numerical values in $\{0, 1\}$. Then, each value $c_j$ of the original categorical feature is represented by a bit-value assignment to the new $k$ binary features in which the $j$-th feature is set to 1 and the remaining $k - 1$ binary features are set to 0.

Classifiers can be evaluated and compared through several metrics. A basic metric is accuracy on a test dataset: given a ground truth test dataset $T \subseteq X \times L$, the accuracy of a classifier $C$ on $T$ is

$$\text{acc}_T(C) \doteq \frac{|\{(x,y) \in T \mid C(x) = \{y\}\}|}{|T|}.$$  

According to a growing belief [22], however, accuracy is not enough in machine learning, since robustness to adversarial inputs of a ML classifier may significantly affect its safety and generalization properties [12, 22]. Given an input perturbation modeled by a function $P : X \rightarrow \phi(X)$, a classifier $C : X \rightarrow \phi_+(L)$ is stable [36] on the perturbation attack $P(x)$ of $x \in X$ when $C$ consistently assigns the same label(s) to every attack ranging in $P(x)$, i.e.,

$$\text{stable}(C, x, P) \doteq \forall x' \in P(x) : C(x') = C(x).$$  \hspace{1cm} (1)

When the sample $x \in X$ has a ground truth label $y_x \in L$, robustness of $C$ on $x$ for attacks in $P(x)$ boils down to stability, i.e. stable$(C, x, P)$ holds, together with correct classification, i.e.
2.2 Decision Trees and Tree Ensembles

We consider standard decision tree classifiers commonly referred to as CARTs (Classification And Regression Trees) [8]. A decision tree \( t : X \rightarrow \varphi_+(L) \) is defined inductively. A base tree \( t \) is a single leaf \( \lambda \) storing a (normalized) frequency distribution of labels for the samples of the training dataset, hence \( \lambda \in [0, 1]^{|L|} \), or, equivalently, \( \lambda : L \rightarrow [0, 1] \). Some algorithmic rule converts this frequency distribution into a set of labels, typically as \( \arg \max_{y \in L} \lambda(y) = \varphi_+(L) \).

A composite tree \( t \) is \( \Gamma(\text{split}, t_i, t_r) \), where \( \text{split} : X \rightarrow \{t, \#\} \) is a Boolean split criterion for the internal parent node of its left and right subtrees \( t_i \) and \( t_r \), respectively; thus, for all \( x \in X \), \( t(x) = \# \) if \( \text{split}(x) \) then \( t_i(x) \) else \( t_r(x) \). Although split rules can be of any type, most common decision trees employ univariate hard splits of type \( \text{split}(x) = x_i \leq k \), for some feature \( i \in [1,d] \) and threshold \( k \in \mathbb{R} \).

Tree ensembles, also known as forests, are sets of decision trees which together contribute to formulate a unique classification output. Training algorithms as well as methods for computing the final output label(s) vary among different tree ensemble models. Random forests (RFs) [7] are a major instance of tree ensemble where each tree of the ensemble is trained independently from the other trees on a random subset of the features. Gradient boosted decision trees (GBDTs) [20] represent a different training algorithm where an ensemble of trees is incrementally built by training each new tree on the basis of the data samples which are mis-classified by the previous trees. For RFs, the final classification output is typically obtained through a voting mechanism (e.g., majority voting), while GBDTs are usually trained for binary classification problems and use some binary reduction scheme, such as one-vs-all or one-vs-one, for multi-class classification.

2.3 Abstract Interpretation Basics

A numerical abstract domain is a tuple \( (A, \subseteq^A, \gamma^A) \) where \( (A, \subseteq^A) \) is at least a preordered set of abstract values and the concretization function \( \gamma^A : A \rightarrow \varphi(\mathbb{R}^d) \), mapping abstract values to sets of numerical vectors, monotonically preserves the ordering relation \( \subseteq^A \), that is, \( a_1 \subseteq^A a_2 \) implies \( \gamma^A(a_1) \subseteq \gamma^A(a_2) \). The intuition is that an abstract domain \( A \) defines a symbolic abstract representation of sets of vectors ranging in the concrete domain \( \varphi(\mathbb{R}^d) \). Known examples of numerical abstract domains used in machine learning verification include intervals, zonotopes, and octagons (see the survey [44]).

Given a concrete \( k \)-ary operation on vectors \( f : (\mathbb{R}^d)^k \rightarrow \mathbb{R}^d \), for some \( k \in \mathbb{N} \), an abstract function \( f^A : A^k \rightarrow A \) is called a sound (or correct) (over-)approximation of \( f \) when, for all \( (a_1, ..., a_k) \in A^k \), \( f(x_1, ..., x_k) \) satisfies \( f^A(a_1, ..., a_k) \subseteq \gamma^A(f(x_1, ..., x_k)) \). Equality holds, \( f^A \) is defined to be complete. In words, this means that soundness holds when \( f^A(a_1, ..., a_k) \) never misses a concrete computation of \( f \) on some input \((x_1, ..., x_k)\) which is abstractly represented by \((a_1, ..., a_k)\), while completeness implies that each abstract computation \( f^A(a_1, ..., a_k) \) is precisely a symbolic abstract representation in \( A \) of the set of computations of \( f \) on all the concrete inputs that are abstractly represented by \((a_1, ..., a_k)\).

We will use the well-known abstract domain of not necessarily closed real \( d \)-dimensional hyper-rectangles \( \mathbb{R}^d \), commonly called interval or box abstraction in abstract interpretation [15, 38]. For concrete vectors ranging in \( \mathbb{R}^d \), the abstract values of \( \mathbb{R}^d \) are \( d \)-dimensional vectors of type

\[
\begin{align*}
\langle l_1, u_1 \rangle, ..., \langle l_d, u_d \rangle & \in \mathbb{R}^d
\end{align*}
\]

where lower and upper bounds \( l_i, u_i \in \mathbb{R} \) for some \( i \in [1,d] \). Thus, the concretization function is defined by \( \gamma(\mathbb{R}^d)(h) \triangleq \{ x \in \mathbb{R}^d | \forall i. l_i \leq x_i \leq u_i \} \). We recall that \( \gamma(\mathbb{R}^d)(\mathbb{R}^d) \) is a complete lattice for the componentwise ordering: \( \langle |l_1, u_1|, ..., |l_d, u_d| \rangle \subseteq \mathbb{R}^d \) iff for all \( i, l_i' \leq l_i \) and \( u_i' \leq u_i \). More on this abstract domain can be found, e.g., in [15, 38].

3 INDIVIDUAL FAIRNESS

Dwork et al. [18, Section 1.1] define individual fairness as "the principle that two individuals who are similar with respect to a particular task should be classified similarly." They formalize this notion as a Lipschitz condition of the classifier, which requires that any two individuals \( x, y \in X \) whose distance is \( \delta(x, y) \in [0,1] \) be mapped to distributions \( D_x \) and \( D_y \), respectively, such that the distance between \( D_x \) and \( D_y \) is at most \( \delta(x, y) \). The intuition is that the output distributions for \( x \) and \( y \) are indistinguishable up to their distance. The distance metric \( \delta : X \times X \rightarrow \mathbb{R}_{\geq 0} \) is problem specific, and for their applications Dwork et al. [18, Section 2] study the total variation or relative \( \ell_\infty \) distances.

By following Dwork et al.'s standard definition [18, Section 2], we consider a classifier \( C : X \rightarrow \varphi_+(L) \) to be fair when \( C \) outputs the same set of labels for every pair of individuals \( x, y \in X \) which satisfy a similarity relation \( S \subseteq X \times X \) between input samples. Thus, \( S \) can be derived from any distance \( \delta \) as \( (x, y) \in S \Leftrightarrow \delta(x, y) \leq \tau \), where \( \tau \in \mathbb{R} \) is a threshold of similarity. In order to provide a fairness metric for a classifier \( C \), we count how often \( C \) is fair on sets of similar individuals ranging into a test dataset \( T \subseteq X \times L \):

\[
\begin{align*}
\text{fair}_T(S)(C) & \triangleq \frac{|\{(x, y) \in T | \text{fair}(C, x, S)\}|}{|T|}
\end{align*}
\]

(2)

where \( \text{fair}(C, x, S) \) is defined as follows:

**Definition 3.1 (Individual Fairness).** A classifier \( C : X \rightarrow \varphi_+(L) \) is fair on an individual \( x \in X \) with respect to a similarity relation \( S \subseteq X \times X \), denoted by \( \text{fair}(C, x, S) \), when

\[
\forall x' \in X : \langle x, x' \rangle \in S \Rightarrow C(x') = C(x).
\]

Hence, fairness for a similarity relation \( S \) boils down to stability on the perturbation \( P_S(x) \) is \( \{ x' \in X | \langle x, x' \rangle \in S \} \) (cf. Equation (1) in Section 2.1), namely, for all \( x \in X \),

\[
\text{fair}(C, x, S) \Leftrightarrow \text{stable}(C, x, P_S).
\]

(3)

Let us remark that fairness is orthogonal to accuracy since it does not depend on the correctness of the label assigned by the classifier, so that training algorithms that maximize accuracy-based metrics do not necessarily achieve fair models. Thus, this is also the case of a natural learning algorithm for CART trees and random
forests, that locally optimizes split criteria by measuring entropy or Gini impurity, which are both indicators of the correct classification of training data.

It is also worth observing that fairness is anti-monotonic w.r.t. the logical implication of similarity relations, meaning that

\[ \text{fair}(C, x, S) \land S' \subseteq S \Rightarrow \text{fair}(C, x, S'). \]  

(4)

We will exploit this anti-monotonicity property, since it implies that, on one hand, fair classification is preserved for finer similarity relations and, on the other hand, fairness verification and fair training is more challenging for coarser similarity relations.

4 VERIFYING INDIVIDUAL FAIRNESS

As individual fairness is equivalent to stability, we verify individual fairness of ensembles of decision trees by means of Silva [36], an abstract interpretation-based algorithm for checking stability properties of decision tree ensembles.

4.1 Sound and Complete Verification

Silva performs a static analysis of an ensemble of decision trees leveraging an abstract domain \( A \) that approximates computations on real vectors. Each abstract value \( a \in A \) symbolically represents a set of real vectors \( y^A(a) \in \wp(\mathbb{R}^d) \). Then, Silva over-approximates an input region \( P(x) \in \wp(\mathbb{R}^d) \) for an input vector \( x \in \mathbb{R}^d \) by an abstract value \( a \in A \) such that \( P(x) \subseteq y^A(a) \), and for each decision tree \( t \), it computes an over-approximation of the set of leaves of \( t \) that can be reached from some vector in \( y^A(a) \). This is computed by collecting the constraints of all the split nodes in each root-leaf path of \( t \), so that each leaf \( \lambda \) of \( t \) stores the minimum set of constraints \( C_\lambda \) that makes \( \lambda \) reachable from the root of \( t \). The verification algorithm then checks whether this set of constraints \( C_\lambda \) can be satisfied by the input abstract value \( a \in A \): this check \( a \models^? C_\lambda \) must be sound, meaning that if some input sample \( x \in X \) abstractly represented by \( a \), i.e. \( x \in y^A(a) \), actually reaches the leaf \( \lambda \), then \( a \models C_\lambda \) must necessarily hold. When \( a \models C_\lambda \) holds the leaf \( \lambda \) is marked as reachable from the abstract value \( a \).

Example 4.1 (Sound verification). Consider the scenario in Fig. 1 where the set of split constraints for some leaf \( \lambda \) is \( C_\lambda = \{ x_1 \leq 2, -(x_1 \leq -1), x_2 \leq -1 \} \), depicted in blue. An hyper-rectangle abstract value such as \( h = \{ x_1 \leq 0, x_2 \leq 0 \} \) in \( \mathbb{HR}_d \), depicted in green, abstractly represents some points which satisfy all the constraints in \( C_\lambda \), so that \( a \models C_\lambda \) must hold. On the other hand, for a relational abstract value such as the line \( a \equiv x_1 + x_2 = 4 \), depicted in red, we have that no point in the line satisfies \( C_\lambda \), so that no sure information could be inferred from a merely sound check of \( a \models^? C_\lambda \).

This sound approach therefore provides an over-approximation of the set of leaves of \( t \) reachable from an abstract value \( a \) that allows us to compute a set of labels \( t^*(a) \in \wp(\mathcal{L}) \) which is an over-approximation of the actual set of labels assigned by \( t \) to all the input vectors ranging in \( y^A(a) \), i.e.,

\[ \bigcup_{x \in y^A(a)} t(x) \subseteq t^*(a) \]  

(5)

holds. Thus, given a similarity relation \( S \subseteq X \times X \), it turns out that for all \( x \in X \) and \( a \in A \),

\[ P_S(x) \subseteq y^A(a) \land t^*(a) = t(x) \Rightarrow \text{fair}(t, x, S), \]

meaning that we have a sound verification method for individual fairness of decision trees.

For the most common classification trees with hard univariate splits of type \( x_i \leq k \), it turns out that the abstract domain \( \mathbb{HR}_d \) guarantees that for each leaf constraint \( C_\lambda \) and hyper-rectangle \( h \in \mathbb{HR}_d \), the check \( h \models^? C_\lambda \) is sound and complete, meaning that

\[ h \models C_\lambda \Rightarrow \exists x \models \text{fair}(t, x, S_\lambda). \]

This noteworthy completeness property of the hyper-rectangle abstraction entails that the set of labels \( t^*(h) \) computed by the analysis on \( \mathbb{HR}_d \) coincides exactly with the set of classification labels computed by \( t \) for all the samples in \( y^{\mathbb{HR}_d}(h) \), i.e., the set inclusion in Equation (5) is strengthened to a set equality.

Thus, for the \( t_\infty \)-based similarity relation \( S_\infty \subseteq \mathbb{R}^d \times \mathbb{R}^d \) between individuals, for each input \( x \in \mathbb{R}^d \) there exists a hyper-rectangle \( h_x \in \mathbb{HR}_d \) such that \( S_\infty(x) = \{ x' \in X \mid ||x - x'||_\infty \leq \tau \} = y^{\mathbb{HR}_d}(h_x) \) holds and, in turn, we have that

\[ t^*(h_x) = t(x) \Rightarrow \exists x \models \text{fair}(t, x, S_\infty). \]

Hence, we devised a complete verification method for individual fairness with respect to \( t_\infty \)-based similarity.

Verification of Forests. In order to analyse a forest \( F \) of trees, Silva reduces the whole forest to a single tree \( t_F \), by stacking every tree \( t \in F \) on top of each other, i.e., each leaf becomes the root of the next tree in \( F \), where the ordering of this stacking operation does not affect the output of a forest verification. Then, each leaf \( \lambda \) of this stacked single tree \( t_F \) collects all the constraints of the leaves of trees in the path from the root of \( t_F \) to \( \lambda \). An example is shown in Fig. 2, where the trees \( t_1, t_2, t_3 \) are combined into a single tree, emphasizing how the leaves of the original trees \( t_i \) become internal nodes in this stacked tree \( t_F \), while their sets of constraints are collected and stored in the new leaves of \( t_F \).

Since the stacked tree \( t_F \) suffers from a combinatorial explosion of the number of leaves, Silva deploys a number of optimisation strategies for performing its abstract interpretation. The most relevant ones include a best-first search algorithm to look for a pair of input samples in \( y^A(a) \) which are differently labeled. If one such pair \( x, x' \in y^A(a) \) can be found then unfairness of the forest \( F \) in classifying \( x \) and \( x' \) is proved and the analysis is terminated, otherwise fairness holds. A further optimisation consists in combining
sound analyses with complete ones. While exploring an internal node \( n \), a fast sound but possibly incomplete analysis of \( t_F \) is used to estimate a superset of the leaves of \( t_F \) reachable from \( n \), which, in turn, allows us to compute a superset of the output labels. If such superset consists of a single label, then every leaf reachable from \( n \) necessarily yields that same label, and the rest of the visit of the subtree rooted in \( n \) can be safely omitted; otherwise, that information provided by the node \( n \) is nonetheless used to refine the analysis of \( t_F \). We refer to \cite{36} for further details on Silva.

### 4.2 Verification with One-Hot Encoding

As described above by the equivalence (6), when the similarity relation is defined by the \( \ell_\infty \) norm and the abstract domain of hyper-rectangles \( \text{HR}_d \) is used, our verification method for individual fairness turns out to be complete. However, completeness does not hold for classification problems involving categorical features, as shown by the following simple example.

**Example 4.2 (Incompleteness of one-hot encoding).** The following diagram depicts a toy forest \( F \) consisting of two trees \( t_1 \) and \( t_2 \), where left/right branches are followed when the split condition is false/true.

\[
\begin{align*}
\text{color} & \leq 0.5 & \text{color} & \leq 0.5 \\
\ell_1 & \quad \ell_2 & \ell_2 & \quad \ell_1 \\
t_1 & \quad t_2
\end{align*}
\]

Here, a categorical feature \( \text{color} \in \{\text{white}, \text{black}\} \) is one-hot encoded by \( \text{color}_{\text{white}}, \text{color}_{\text{black}} \in \{0,1\} \). Since colors are mutually exclusive, every white individual in the input space, i.e., a vector \( \langle \text{color}_{\text{white}} = 1, \text{color}_{\text{black}} = 0 \rangle \), will be labeled \( t_1 \) by both trees \( t_1 \) and \( t_2 \). Our fairness verification method on the input \( \ell_{\infty} \)-based similarity relation \( \langle \text{color}_{\text{white}} \in [0,1], \text{color}_{\text{black}} \in [0,1] \rangle = [0,1] \times [0,1] \), which is a hyper-rectangle, infers that the forest \( F \) is unfair on the individual \( \langle \text{color}_{\text{white}} = 1, \text{color}_{\text{black}} = 0 \rangle \) because there exists an input sample \( \text{cex} \in [0,1] \times [0,1] \) such that \( F(\text{cex}) = \{t_1, t_2\} \neq \{t_1\} = F(\text{in}) \). This is due to the counterexample \( \langle \text{cex} = (0,0) \in [0,1]^2 \rangle \) which is therefore similar to \( \text{in} \), although it does not represent any actual individual in the input space. Indeed, \( t_1(\text{cex}) = \{t_1\} \) and \( t_2(\text{cex}) = \{t_1\} \), so that, by a majority voting, \( F(\text{cex}) = \{t_1, t_2\} \), thus making \( F \) unfair on \( \text{in} \), i.e., unfair on white individuals.

To overcome this issue with one-hot encoding, we use a refined abstract domain which is designed as a reduced product\(^1\) of the underlying main abstract domain, in our case the hyper-rectangle abstraction \( \text{HR}_d \), with a relational abstract domain that keeps track of the relationships among the multiple binary features introduced by one-hot encoding categorical features. More formally, this relational abstract domain maintains the following two additional constraints on the \( k \) features \( x^1_1, \ldots, x^1_k \) introduced by one-hot encoding a categorical variable \( x^1 \) with \( k \) distinct values:

(a) the possible values for each \( x^1_i \) are restricted to the discrete set \( \{0,1\} \) (rather than ranging in the continuous interval \([0,1]\));

(b) the sum of all the \( x^1_i \)’s must satisfy the relational constraint \( \sum_{i=1}^{k} x^1_i = 1 \).

Therefore, these conditions (a)-(b) guarantee that any abstract value for \( x^1_1, \ldots, x^1_k \) represents precisely a feasible category for \( x^1 \). This abstract domain for a categorical variable \( x \) with \( k \) distinct values is denoted by \( \text{OH}_k(x) \). In the example above, any hyper-rectangle \( \langle \text{color}_{\text{white}} \in [0,1], \text{color}_{\text{black}} \in [0,1] \rangle \) is reduced by \( \text{OH}_2(\text{color}) \), so that just two distinct abstract values \( \langle \text{color}_{\text{white}} = 0, \text{color}_{\text{black}} = 1 \rangle \) and \( \langle \text{color}_{\text{white}} = 1, \text{color}_{\text{black}} = 0 \rangle \) are allowed.

Summing up, we employed a reduced hyper-rectangle abstract domain, denoted by \( \text{HR}_d \odot \text{OH} \), whose generic abstract value for data vectors consisting of \( d \) numerical variables \( x^1 \in \mathbb{R} \) and \( m \) categorical variables \( c^1 \) with \( k_j \in \mathbb{N} \) distinct categories is:

\[
\langle x^1 \in [l_j, u_j])^d \times (c^1_j \in [0,1] | \sum_{i=1}^{k_j} c^1_i = 1) | j \in [1, m] \rangle \in \text{HR}_d \odot \text{OH},
\]

where \( l_j, u_j \in \mathbb{R} \cup \{-\infty, +\infty\} \) and \( l_j \leq u_j \).

### 5 FAIRNESS-AWARE TRAINING OF TREES

Several algorithms for training robust decision trees and ensembles thereof have been put forward in the literature\(^2\) [2, 10, 11, 13, 26, 37]. These algorithms encode the robustness of a tree classifier as a loss function which is minimized either by exact methods such as MILP or by suboptimal heuristics such as genetic algorithms.

The robust learning algorithm Meta-Silva, introduced in \cite{37}, aims at maximizing a tunable weighted linear combination of accuracy and stability metrics, therefore, thanks to the equivalence (3),

\(^1\)Readers can find more details on reduced products of abstract domains, e.g., in \cite{15}.
instantiating to a combination of accuracy and individual fairness for our purposes. Meta-Silvae relies on a genetic algorithm for evolving a population of decision trees \( t \) which are ranked by their accuracy \( \text{acc}_D(t) \) and individual fairness \( \text{fair}_{D,S}(t) \) w.r.t. a training dataset \( D \), where the individual fairness metric \( \text{fair}_{D,S}(t) \) for a similarity relation \( S \) is computed by the verification method described in Section 4.1. At the end of the genetic evolution, the best tree (or best trees are) is returned. It turns out that Meta-Silvae typically outputs significantly compact models and often achieves high accuracy and fairness already with a single decision tree rather than a forest of them. Thus, the instantiation of Meta-Silvae to the reduced product abstract domain HRQ @ OH described in Section 4.2 provides a learning algorithm for ensembles of decision trees, called FATT, that enhances their individual fairness.

More specifically, the objective function \( \varphi \) of FATT, for learning fair decision trees, is given by a weighted sum of the accuracy and individual fairness scores over the training dataset \( D \), i.e.,

\[
\varphi_D(t) = w_a \cdot \text{acc}_D(t) + w_f \cdot \text{fair}_{D,S}(t).
\]

We use \( w_a = 0.9 \) and \( w_f = 0.1 \) for all our experiments (presented in the next section).

While standard learning algorithms for tree ensembles require tuning a number of hyper-parameters, such as maximum depth of trees, minimum amount of information on leaves and maximum number of trees, FATT is able to infer them automatically, so that the customary tuning process is not needed. Instead, some standard parameters are required by the underlying genetic algorithm, notably, the size of the evolving population, the maximum number of evolving iterations, the selection of crossover and mutation functions [25, 42]. It should be remarked that, given an objective function, the genetic algorithm of FATT converges to an optimal (or suboptimal) solution regardless of the chosen parameters of the genetic algorithm, which just affect the rate of convergence and therefore should be chosen for tuning its convergence speed only.

Crossover and mutation functions are the two main features of the genetic algorithm of FATT. The crossover function combines two parent trees \( t_1 \) and \( t_2 \) of the current evolving population by randomly substituting a subtree of \( t_1 \) with a subtree of \( t_2 \). After a crossover operation, two types of mutation strategies are available: grow-only, which only allows trees to grow, and grow-and-prune, which also allows pruning the mutated trees. We just sketch an example of crossover and mutation functions and refer to [37] for a detailed definition.

**Example 5.1 (Crossover and mutation).** Fig. 3 depicts a simple example of crossover, where every node is represented by a tuple \((i, k, R)\), with \( i, k \) denoting a split \( x_j \leq k \) (therefore not relevant for the training set), while \( R \subseteq X \) represents the subset of samples in the training set reaching that node. The crossover tree \( t_{cross} \) is built by selecting the subtree \( s_2 \) of \( t_1 \) given by the leaf \((\ldots, R_4)\) only, the subtree \( s_3 \) of \( t_2 \) rooted at node \((2, 1, R_5)\), and by replacing \( s_1 \) with \( s_2 \) in \( t_1 \). Selection of both subtrees can be fully random, or relies on some mixed heuristic/stochastic criteria, for example by replacing a poorly performing subtree with a better one from another tree, where subtrees are stochastically selected with a probability proportional to their Gini impurity. While the split constraints \( x_j \leq k \) are directly copied from the donor tree, the set \( R \) of reaching samples may well be different, and must therefore be recomputed. After a crossover operation, it may happen that the set of reachable samples \( R \) of some node \( n \) of \( t_{cross} \) becomes empty, thus making \( n \) unreachable. In this case, the tree is pruned by removing these unreachable nodes and by replacing their parents with the siblings. In Fig. 3, \( t_{prune} \) is the result of pruning the leaf \((\ldots, R_3 = \emptyset)\) of \( t_{cross} \).

Fig. 3 also depicts two mutations of \( t_{cross} \): \( t_{mute} \) is obtained from \( t_{cross} \) by expanding the leaf \((\ldots, R_7)\), while \( t_{mute} \) prunes the subtree rooted at \((2, 1, R_1)\). In both cases, the leaf to grow or the subtree to prune can be selected randomly or stochastically with a probability proportional to Gini impurity.

**FATT.** Let us recall that the standard learning method for CART trees [8] is a greedy algorithm which incrementally builds a decision tree by locally computing new split nodes or new leaves, where a new split \( x_j \leq k \) is inferred by testing every possible combination of \( i \) and \( k \) in order to locally minimize a Gini impurity or entropy index. It is also worth recalling that while this greedy learning approach yields trees which are very accurate on the training set, it often leads to overfitting, a well-known phenomenon with decision trees [6].

FATT relies on an objective function that takes into account both accuracy and individual fairness, cf. Equation (7). Thus, in FATT the
selection of a candidate split relies on an individual fairness index $\text{fair}_{D_s}(t)$ computed by the verifier described in Section 4.1 on the whole corresponding candidate tree $t$. This learning process is inherently not incremental and consequently could be computationally burdensome. Such a computational cost is alleviated by introducing a search aggressiveness parameter which sets up a bound on the number of new split candidates to consider or a timeout mechanism. It turns out that this optimization is effective in reducing the computational burden without sacrificing the overall generalization, because the evaluation of split candidates which are ruled out is simply delayed to later iterations of the evolutionary process.

Our fair learning method FATT uses the following basic parameters for the underlying genetic algorithm Meta-Silvae: the population size is kept fixed to 32, as our experimental evaluation showed that this provides an effective balance between achieved individual fairness and training time; the standard roulette wheel algorithm [32] is employed as selection function (which is proportional to the objective function $\phi$); the number of iterations of the evolutionary process is typically dataset-specific and can be estimated by running a preliminary analysis of the convergence speed, for instance by stopping after a given number of iterations with no improvement.

6 EXPERIMENTAL EVALUATION

We consider the main standard datasets used in the fairness literature [31] and we preprocess them by following the steps of Ruoss et al. [40, Section 5] for their experiments on individual fairness for deep neural networks: (1) standardize numerical attributes to zero mean and unit variance; (2) one-hot encoding of all categorical features; (3) drop rows/columns containing missing values; (4) split into train and test set. These datasets concern binary classification tasks, although our fair learning algorithm naturally extends to multiclass classification with no specific effort. The source code of FATT as well as all the datasets and preprocessing pipelines are publicly available on GitHub [35].

**Adult.** The Adult income dataset [17] is extracted from the 1994 US Census Database. Every sample assigns a yearly income (below or above 50K US$) to an individual based on personal attributes such as gender, race, and occupation.

**Compas.** The COMPAS dataset contains data collected on the use of the COMPAS risk assessment tool in Broward County, Florida [3]. Each sample predicts the risk of recidivism for individuals based on personal attributes and criminal history.

**Crime.** The Communities and Crime dataset [17] contains socio-economic, law enforcement, and crime data for communities within the US. Each sample indicates whether a community is above or below the median number of violent crimes per population.

**German.** The German Credit dataset [17] contains samples assigning a good or bad credit score to individuals.

**Health.** The heritage Health dataset (https://www.kaggle.com/c/hbp) contains physician records and insurance claims. Each sample predicts the ten-year mortality (above or below the median Charlson index) for a patient.

The following table displays size and distribution of positive samples for these datasets.

</tbody>
</table>

As noticed by Ruoss et al. [40], some datasets exhibit a highly unbalanced label distribution. For example, for the Adult dataset, a constant classifier $C(x) = 1$ would achieve 75.4% test set accuracy and 100% individual fairness with respect to any similarity relation. Hence, we follow [40] and we additionally evaluate and report the balanced accuracy of our FATT classifiers, i.e.,

$$0.5 \left( \frac{\text{truePositive}}{\text{truePositive} + \text{trueNegative}} + \frac{\text{trueNegative}}{\text{trueNegative} + \text{truePositive}} \right).$$

6.1 Similarity Relations

Following Ruoss et al. [40, Section 5.1], we consider four different types of similarity relations. In the following, let $I \subseteq \mathbb{N}$ denote the set of indexes of features of an individual after one-hot encoding.

**Noise:** Two individuals $x, y \in X$ are similar when a subset of their (standardized) numerical features indexed by a given subset $I' \subseteq I$ differs less than a given threshold $\tau \geq 0$, while all the other features are unchanged: $(x, y) \in S_\text{noise}$ iff $|x_i - y_i| \leq \tau$ for all $i \in I'$, and $x_i = y_i$ for all $i \in I \setminus I'$. For our experiments, we consider $\tau = 0.3$ in the standardized input space, e.g., for Adult two individuals are similar if their age difference is at most 3.95 years.

**Cat:** Two individuals are similar if they are identical except for one or more categorical sensitive attributes indexed by $I' \subseteq I$: $(x, y) \in S_\text{cat}$ iff $x_i = y_i$ for all $i \in I \setminus I'$. For Adult and German, we select the gender attribute. For Compas, we identify race as sensitive attribute. For Crime, we consider two individuals similar regardless of their state. Lastly, for Health, neither gender nor age group should affect the final prediction.

**Noise-cat:** Given noise and categorical similarity relations $S_\text{noise}$ and $S_\text{cat}$, their union $S_\text{noise-cat} \triangleq S_\text{noise} \cup S_\text{cat}$ models a relation where two individuals are similar when some of their numerical attributes differ up to a given threshold while the other attributes are equal except some categorical features.

**Conditional-attribute:** Here, similarity is a disjunction of two mutually exclusive cases. Consider a numerical attribute $x_i$, a threshold $\tau \geq 0$ and two noise similarities $S_n_1, S_n_2$. Two individuals are defined to be similar if either their $i$-th attributes are similar for $S_n_1$ and are bounded by $\tau$ or these attributes are above $\tau$ and similar for $S_n_2$: $S_\text{cond} \triangleq \{(x, y) \in S_n_1 | x_i \leq \tau, y_i \leq \tau\} \cup \{(x, y) \in S_n_2 | x_i > \tau, y_i > \tau\}$. For Adult, we consider the median age as threshold $\tau = 37$, and two noise similarities based on age with thresholds 0.2 and 0.4, which correspond to age differences
of 2.63 and 5.26 years, respectively. For German, we also consider the median age $\tau = 33$ and the same noise similarities on age, that correspond to age differences of 0.24 and 0.47 years.

It is worth remarking that our fairness-aware learning algorithm is not limited to support these similarity relations. Further domain-specific similarities can be defined and handled by our approach by simply instantiating the underlying fairness verifier with a suitable over-approximating abstract domain $\mathcal{A}$ to retain a sound verification. Moreover, if the similarity relation can be precisely represented in $\mathcal{A}$, completeness is preserved as well.

### 6.2 Setup

Our experimental evaluation compares CART trees and Random Forests with our FATT tree models. CARTs and RFs are trained by scikit-learn. We first run a preliminary phase for tuning the hyper-parameters for CARTs and RFs. In particular, we considered both entropy-based information gain and Gini index as split criteria, and we checked maximum tree depths ranging from 5 to 100 with step 10. For RFs, we scanned the maximum number of trees ranging from 5 to 100, step 10. Cross validation inferred the optimal hyper-parameters, where the datasets have been split in 80% training and 20% validation sets. The hyper-parameters of FATT (i.e., weights of accuracy $w_\text{a}$ and fairness $w_f$ in the objective function (7), type of mutation strategy, number of iterations) are inferred by assessing convergence speed, maximum fitness value and variance among fitness in the evolving population during the training phase. We report here the best results, obtained with $w_\text{a} = 0.9$ and $w_f = 0.1$. The number of evolutionary iterations for the experiments ranges between 10 and 100. Specifically, we obtained the best results with 10 iterations for the Crime and German datasets, and with 100 iterations for Adult, Compas, and Health. It turned out that accuracy and fairness of single FATT trees, rather than forests, were already competitive, with individual fairness exceeding 85% for the most challenging similarities. We therefore concluded that ensembles of FATT trees do not introduce statistically significant benefits over single decision trees. Since FATT trees are stochastic, by relying on random seeds, each experimental test has been repeated 1000 times and the reported results refer to their median value.

### 6.3 Results

Table 1 provides a comparison between RF and FATT models by showing accuracy, balanced accuracy and individual fairness with respect to the four similarity relations of Section 6.1 computed on the test sets $T$. The conditional-attribute similarity relation only applies to the Adult and German datasets. As expected, FATT decision trees are slightly less accurate than RFs — about $-3.6\%$ on average, which also reflects to balanced accuracy — but outperform RFs in every fairness test. On average, the fairness increment ranges between $+32.09\%$ to $+43.91\%$ among the noise, cat, and noise-cat similarity relations. For the conditional-attribute similarity the average fairness increase of FATT models is $+8.68\%$.

Fig. 4 shows the distribution of accuracy and individual fairness for FATT trees over 1000 runs of the FATT learning algorithm. This boxplot is for fairness with respect to noise-cat similarity, as this is the most challenging relation for achieving individual fairness, as a consequence of anti-monotonicity (4). We observe a stable behaviour for accuracy, with about 50% of the observations lying within one percentile from the median. The results for fairness are similar, although for Compas we report a higher variance of the distribution, where the lowest fairness percentage is about 10% higher than the corresponding one for RFs. We claim that this may depend on the high number of features in the dataset Compas, which makes fair training a challenging task.

Table 2 compares the size of RF and FATT models, defined as total number of leaves, and their average verification time of individual fairness per input sample. It turns out that FATT tree models are orders of magnitude smaller and, therefore, more interpretable than RFs, while the average verification time per sample for our FATT models is always negligible ($< 0.1$ milliseconds).

Finally, Table 3 compares FATT models with natural CART trees in terms of accuracy, individual fairness with respect to the noise-cat similarity, and size. While CARTs are approximately $3\%$ more accurate than FATT models on average, they are roughly half less fair and more than $10\times$ larger.

**CART with Hints.** As already recalled, decision trees frequently overfit [6] due to their high number of leaves, thus yielding unstable/unfair models. Post-training techniques, such as tree pruning, are commonly used to mitigate overfitting [28], although they are deployed when a tree has been already fully trained and, therefore, pruning is often poorly beneficial. As a byproduct of our fairness-aware learning approach, we trained a set of natural CART trees, denoted by CART with Hints in Table 3, which exploit hyper-parameters as “hinted” by our FATT training. In particular, in this learning of CART trees with hints, the maximum tree depth and the minimum number of samples per leaf are obtained as tree depth and minimum number of samples of our best FATT models. Interestingly, the results in Table 3 show that these decision trees with hints have roughly the same size of our FATT trees, are approximately $20\%$ more fair than natural CART trees and just $1\%$ less accurate. Overall, it turns out that the general performance of these CARTs with hints is halfway between natural CARTs and FATT trees, both in term of accuracy and individual fairness, while having the same compactness of FATT models.

### 7 Conclusion

We believe that this work contributes to push forward the use of formal verification methods in decision tree learning, in particular a well known program analysis technique such as abstract interpretation is proved to be successful for training and verifying decision tree classifiers which are both accurate and fair, improve on state-of-the-art CART and random forest models, while being much more compact and thus interpretable. We also showed how information from our FATT trees can be exploited to tune the natural training process of decision trees. As future work we plan to extend our fairness verification and learning method by considering alternative fairness definitions, such as group or statistical fairness, or stronger notions such as causal [21] or dependency [43] fairness. We also aim at designing quantitative verification methods for both stability and fairness, in order to provide probabilistic guarantees on the behavior of decision tree and tree ensemble models.
